The research results of the process of lisakovskiy gravitational magnetic concentrate (LGMC) solid-phase metallization using the highly reactive solid carbon reducing agent «direksil» are given in the article. There were set rational parameters of solid-phase reduction process of LGMC in the mine furnace providing the extent of its metallization of 20.4–88.6 %. It was determined the temperature range of solid-phase direct reduction of iron of 1150–1200 ºC providing the maximum rate and extent of iron oxides metallization, at the same time passing over emergence of the liquid phase — fusion. Use of «direksil» as a reducing agent allows raising metallization extent of LGMC in more than 3 times in comparison with furnace coke. In the article there are given diffraction patterns (X-ray patterns) of the metallized samples of LGMC characterizing phase structure and crystal structure of the obtained restoration products depending on the type of reducing agent. The physical condition of the metallization products obtained in the mode of solid-phase restoration allows using all known methods of separation of the metallized concentrate from the dead rock. The most preferable option of such separation includes methods of magnetic separation in view of contrast formed after the system metallization. Separation of magnetic and non-magnetic products after metallization is an obligatory element of the technological scheme of LGMC metallization since the total content of iron in initial concentrate does not exceed 49 %. At that depending on metallization extent the magnetic fraction can be used as a furnace charge component when smelting the conversion iron in the blast furnace (metallization extent is less than 40 %) or steelmaking in the electric furnace (metallization extent is more than 80 %).

**Keywords:** brown iron, LGMC, solid-phase metallization, metallization extent, carbon reducing agent, direksil, phase structure, metallized concentrate.

Many research works and publications are devoted to studies of the iron restoration process from the lisakovskiy gravitational and magnetic concentrate (LGMC) during a number of decades [1–6]. In particular the scientists of Zh. Abishev Chemical and Metallurgical Institute are engaged in solution of the problem of benefication and refinement (dephosphorization) of LGMC [3–6] for many years. In the works [2–6] there are concerned the results of reducing roasting of LGMC with use of gaseous, solid and liquid reducers. Authors [2] established that restoration rate of concentrate’s layer was limited by external diffusion at designed temperature and gas composition. And, as the studies have shown, the external diffusive resistance for a concentrate is much less than internal diffusive resistance, for example, for the iron nugget concentrate, and is regulated by change of gas consumption, due to which the metallization rate increases significantly. This advantage of the concentrate over the layer of lumpy materials can be used for solution of problems of direct metallization of iron ore concentrates, in particular, in vertical porous tanks. But the main obstacle in the way for realization of such process is susceptibility of usual iron ore concentrates to adhesion and swelling during restoration. However, according to authors [2], as for metallization of LGMC, the process proceeds without adhesion of particles even at 1000 ºC. Lisakovskoy concentrates in the whole interval of reduction degree from 0 to 1 do not conglutinate both at low and high (1000 ºC) temperatures, they do not inflate and, on the
contrary, considerably shrink. These features of them are favorable to solution of tasks on solid-phase metal-
lization, with expansion of temperature limits of reduction in order to achieve the high rate of interaction. To
overcome the difficulties connected with low burdening materials’ bed porosity it is necessary to create such
conditions for metallization of ore raw materials at which the rate of the process would not be limited by dif-
fusive resistance. It is possible to solve this important problem when using reducer with the high reactive
capacity and applying the special technology on preparation of burden constituents.

The problem of the real researches consisted in determination of temperature limits of solid-phase direct
reduction of iron with a view to provide the maximum rate and extent of metallization of iron oxides, at the
same time passing over emergence of the liquid phase — fusion. For solution of that we have conducted a
series of experiments on studying the influence of temperature condition on metallization of the lisakovsky
gravitational and magnetic concentrate in the heat-treatment furnace (mine furnace). Test activity on direct
restoration was carried out at 1000–1250 °C temperatures. The furnace coke (Arselor Mittal Temirtau) and
new highly reactive reducer «direksil» were used as reducing agents. Carbonaceous reducing agent
«direksil» was obtained from the enriched nonlinkering coal by the method of high-speed thermal-oxidative
carbonization. Development and exploitation of the production technology of direksil were carried out under
the direction of professor, laureate of state prize of RK V.A. Kim (Zh. Abishev Chemical and Metallurgical
Institute) [7].

Ash technical specifications and chemical composition of the carbonaceous reducers used in the exper-
iments carried out by us are given in the Tables 1 and 2. Weight ratios of LGMC to the reducing agent were
1:0.25. Preparation of furnace charge for metallization was carried out by two ways, namely,
– LGMC and reducing agent (furnace coke or direksil) were placed in the melting pot by layers;
– LGMC and reducing agent (furnace coke or direksil) were carefully mixed and placed in the melting
pot.

| Table 1 |
|-----------------|-----------------|-----------------|-----------------|-----------------|
| Reducing agent | Technical structure, % |     |     |     |
|     | Wkp | A | Vdp | Sdp | Pdp |
| Direksil | 1.0–2.0 | 1.0–5.0 | 3.6–15.0 | 0.20–0.40 | 0.01–0.04 |
| Furnace coke of ArselorMittal Temirtau | 2.0–15.0 | 13.8 | 1.5 | 0.50 | 0.045 |

| Table 2 |
|-----------------|-----------------|-----------------|-----------------|-----------------|
| Reducing agent | Chemical composition of reducing agents' ash |     |     |     |
|     | SiO2 | Al2O3 | MgO+CaO | Fe2O3 |
| Direksil | 48.06 | 18.62 | 4.78 | 7.32 |
| Furnace coke of ArselorMittal Temirtau | 48.50 | 20.0 | 8.7 | 16.6 |

The analysis of experiment results on metallization of LGMC with the use of furnace coke shows that at
long isothermal holding the set temperature of emergence of the liquid phase is 1150 °C. In such a way it was
observed emergence of the liquid phase — fusion (fayalite) in restoration products in the experiments carried
out at the temperature of 1150 °C. Pictures of the metallized samples obtained as a result of reducing roasting
of LGMC with the use of the furnace coke as a reducing agent at long isothermal holding of 60 and 90
minutes at 1150 °C are given in the Figure 1. As you can see on the fracture of the samples the fusion zone
with increase in hold time up to 90 minutes covers almost total volume of the metallized product (sample b).

With reduction of isothermal time of LGMC mixture and solid reducing agent the temperature range of
solid-phase restoration extends towards the greater temperature considerably. So at the time of isothermal
holding of pilot samples within 5–15 minutes the noticeable emergence of the liquid phase was not observed
at 1150 °C and even at 1200 °C. Noted feature of mixture behavior of LGMC and solid reducing agent is in-
dicative of the basic possibility of realization of solid-phase restoration of LGMC at short-term holding of
furnace charge within 10–15 minutes with achievement of the set extent of metallization of ≤40 % as well as
≥80 %. At the same time the subsequent separation of a ferriferous part from dead rock can be carried out by
methods of magnetic separation of products of solid-phase metallization.
The concentrate which is formed at metallization extent of $\leq 40\%$ containing up to $72\%$ of iron can be used at domain melting of conversion iron. It opens a prospect of the wider involvement of brown iron ores into traditional two-stage steel production the balance reserves of which in Kazakhstan are estimated in billions of tons.

According to requirements to a metallized concentrate the criteria of its suitability as a furnace charge component for steel smelting in electric furnaces is metallization extent of more than $80\%$ at the minimum content of dead rock [8]. Results of the experiments carried out in the range of temperatures of 1150–1250 °C showed that it was necessary to apply the highly reactive reducing agent in the form of direksil for achievement of metallization extent of LGMC of $\geq 80\%$. At that in the temperature range of 1200–1250 °C the set metallization extent of LGMC (80 % and more) is provided at mixture holding within 8–10 minutes.

In compliance with a research problem at traditional ways of metallization of LGMC connected with long isothermal holding, as a rule, exceeding 60–90 minutes there were set the technological parameters of solid-phase restoration in which metallization temperature should not exceed 1100 °C. For obvious demonstration of influence of reducing agent type on metallization process of LGMC the results of the experiments carried out at 1100 °C and hold time of 90 minutes are given below. The furnace coke and direksil are considered as the solid reducing agents (see Table 1). Conditions of furnace charge preparation are described below:

- Experiment No. 1 — LGMC and furnace coke were divided into 5 parts and placed in the melting pot by layers.
- Experiment No. 2 — LGMC and direksil were divided into 5 parts and placed in the melting pot by layers.
- Experiment No. 3 — LGMC and direksil were mixed and placed in the melting pot.
- Experiment No. 4 — LGMC and furnace coke were mixed and placed in the melting pot.

The pictures of the metallized product samples of LGMC obtained with different reducing agents are given in the Figure 2.

![Figure 2](image)

Figure 2. Pictures of metallized product samples of LGMC

Products of reducing roasting are represented by weakly caked-on particles, which crumble by easy pressing. Thus, the physical condition of the metallization products obtained in the mode of solid-phase restoration allows using all known methods of separation of the metallized concentrate from the dead rock. And the most preferable option of such separation includes methods of magnetic separation in view of contrast...
formed after the system metallization. Separation of magnetic and non-magnetic products after metallization is an obligatory element of the technological scheme of LGMC metallization since the total content of iron in initial concentrate does not exceed 49 %. At that depending on metallization extent the magnetic fraction can be used as a furnace charge component when smelting the conversion iron in the blast furnace (metallization extent is less than 40 %) or steelmaking in the electric furnace (metallization extent is more than 80 %).

Samples a and b were obtained when loading furnace charge by layers, and samples c and d — as a result of carrying out metallization by furnace charge mixing. Direksil was used as a reducing agent in samples b, d; a and c were obtained with the use of furnace coke. For assessment of reduction degree of iron oxides on height of the metallized sample the test for the chemical analysis was selected by layers. Non-magnetic component of the metallized samples was separated by means of magnetic separation without crushing of the products obtained. The chemical composition of the magnetic part of the metallization products of LGMC is given in the Table 3. According to the results of analysis of the chemical composition of the magnetic component of metallized LGMC content of the total iron in the metallized products with application of direksil is higher than in samples with use of furnace coke for 5–7 abs. %.

</table>

In Figures 3 and 4 there are given diffraction patterns (X-ray patterns) of the metallized samples of LGMC characterizing phase structure and crystal structure of the obtained restoration products depending on the type of reducing agent. It should be noted that the content of silicon dioxide in the samples obtained by mixing the furnace charge before metallization process conduction is less for 3–5 % than in the samples obtained when loading furnace charge by layers that is coordinated with data of X-ray phase analysis (Fig. 3, 4).

As a result of solid-phase restoration in all experiments we have obtained a metallized concentrate in the form of weakly caked-on particles, which crumble by easy pressing. Extent of metallization is calculated according to the chemical analysis taking into account results of X-ray phase analysis. Exponents of metallization of the obtained products depending on conditions of furnace charge preparation for recovery roasting and the applied reducer are given in the Table 4.
Figure 3. Diffraction pattern of the metallized product samples obtained when loading the furnace charge by layers with application of furnace coke (a) and direksil (b) as a reducing agent.

Figure 4. Diffraction pattern of the metallized product samples obtained when mixing the furnace charge with application of furnace coke (a) and direksil (b) as a reducing agent.
According to the chemical analysis (Table 4) the greatest extent of metallization of 85–88 % at the total iron content of 72–77 % was reached in the experiments No. 2 and No. 4, when using direksil as a reducing agent, activity of which is much higher than those of traditionally applied reducers, in particular, of furnace coke. At that the metallization extent in the experiment No. 2 (with direksil) is 3 times higher than in the experiment No. 1 (with furnace coke). Diffraction patterns of the metallized product samples given in Figures 3 and 4 also confirm advantage of using direksil as a reducing agent. Characteristic peaks of metal iron are much more intensive, and presence of fayalite and hercynite, which are formed in the course of the iron oxides recovery, is insignificant (Fig. 3, b and 4, b) in comparison with phase structure of the metallized product obtained with the use of furnace coke (Fig. 3, a and 4, a). The average chemical composition of the metallized samples is as follows $F_{\text{total}} = 77.91$; $SiO_2 = 8.31$; $Al_2O_3 = 6.68$; $MgO = 0.98$; $P = 1.08$. Basicity $(Al_2O_3+MgO)/SiO_2$ is equal to 0.9.

Thus, as a result of conducting studies of the metallization modes of brown iron lisakovskiy concentrate there are set the rational parameters of direct solid-phase restoration of LGMC in the laboratory mine furnace providing extent of its metallization of 20.38–88.64 %. It is more preferable to usedireksil as a reducing agent, highly active solid reducer from Shubarkol coal allowing raising extent of metallization of LGMC in more than 3 times in comparison with furnace coke. Optimum temperature of solid-phase metallization process of LGMC at long holding should not exceed 1100 ºC. With reduction of time of isothermal holding of LGMC mixture with solid reducer the solid-phase metallization is provided at more high temperatures of roasting reaching up to 1150–1200 ºC. The specified feature allows using the new technical solutions for achievement of the set metallization extents of LGMC obtaining the final products for multiple purposes.

Work was performed upon the program of grant financing within the project No. 0026/PTF «Development of autothermal technology of metallized concentrate production from brown iron ores». Report about SRW/ Zh. Abishev ChMIn. Karaganda, 2016.

Исследование процесса твердофазной металллизации буроугольного лисаковского сырья

В статье приведены результаты исследования процесса твердофазной металллизации лисаковского гравитационного магнитного концентрат (ЛГМК) с применением высококерамического углеродного восстановителя «Дирексил». Установлены рациональные параметры процесса твердофазного восстановления ЛГМК в шахтной печи, обеспечивающие степень его металллизации 20,4–88,6 %. Определён температурный диапазон твердофазного прямого восстановления железа 1150–1200 °С, обеспечивший максимальную скорость и степень металллизации оксидов железа, минимизируя при этом появление жидкости фазы — расплава. Использование «Дирексила» в качестве восстановителя позволяет повысить степень металллизации ЛГМК в большее чем 3 раза по сравнению с доменным коксом. Приведены дифрактограммы (рентгенограммы) металллизованных образцов ЛГМК, характеризующие фазовый состав и кристаллическую структуру полученных продуктов восстановления в зависимости от вида восстановителя. Физическое состояние продуктов металллизации, полученных в режиме твердофазного восстановления, позволяет использовать все известные методы разделения металллизованного
концентрат от пустой породы. Причём наиболее предпочтительным вариантом подобного разделения являются приемы магнитной сепарации в виду контрастности образующейся после металллизации системы. Разделение магнитного и немагнитного продуктов после металллизации является обязательным элементом технологической схемы металллизации ЛГМК, так как суммарное содержание железа в исходном концентрате не превышает 49 %. При этом, в зависимости от степени металллизации, магнитная фракция может быть использована как компонент шихты при выплавке передельного чугуна в доменной печи (степень металллизации менее 40 %) или же выплавке стали в электрической печи (степень металллизации более 80 %).

Ключевые слова: буроежелезняковые руды, ЛГМК, твердофазная металллизация, степень металллизации, углеродный восстановитель, «Дирексил», фазовый состав, металллизованный концентрат.
