Analysis of oil sludge and selection of solvents for the extraction method of petroleum products recovery

Analysis of oil sludge formed in a storage tank for straight-run fuel oil of «Pavlodar Oil Chemistry Refinery» LLP was carried out in this work. Content of water, oil products and mechanical impurities was 12.4 %, 17.6 % and 70 %, respectively. A sample of oil separated from the sludge was analyzed for the content of silica gel resins, paraffins and asphaltenes, and their group composition was studied using the IR spectrometry method. It was revealed that the oil sludge stabilizers belonged to the paraffin type. TG/DSC analysis was used to obtain information on the initial and final temperature of the thermal decomposition of the oil sludge. It was shown that oil products are completely burned to a temperature of 600 ºC. This temperature was used for calcining oil sludge. The phase composition of mechanical impurities isolated from the oil sludge was determined by X-ray diffraction analysis. According to the data obtained from X-ray diffraction analysis, main constituents of the mineral part of the oil sludge were quartz sand (63.1 %) and albite (16.5 %). The most optimal mixture of solvents (white spirit: hexane) for extracting petroleum products from the oil sludge was obtained using the extraction method. Keywords: oil sludge, mechanical impurities, solvent, extraction, paraffins, resins, asphaltenes, TG/DSC analysis.

Introduction

Oil sludge is a complex physico-chemical mixture consisting of water, oil products and mechanical impurities (clay, sand, metal oxides). These components are well mixed and stabilized. The oil phase primarily consists of saturated and aromatic hydrocarbons, asphaltenes and resins [1–4]. A significant amount of oil sludge is produced by the oil industry during production, transportation, storage and refinery. In oil refineries, sludge is formed during processes of fluid catalytic cracking, visbreaking, air flotation and wastewater treatment. Oil sludge accumulates in sedimentation tanks and at the bottom of storage tanks, occupying a working volume [3, 5–7]. Storage of oil sludge causes complex environmental problems, while the oil part of it is a valuable organic raw material. As a result of utilization it is possible to obtain such commodity products as hydrocarbon gas, commercial fuel components, lubricants, bitumen etc., as well as recycling products such as uncultivated soil, ash, soot, gaseous components.

Several methods of processing oil sludges are known with the aim of reducing toxicity, minimizing the volume of oil sludge and extracting petroleum products. Flotation, pyrolysis, combustion, biodegradation, freezing/thawing, ultrasonic treatment, electrical processing, microwave radiation and solvent extraction are among them [3, 4]. Their effectiveness depends on the properties of specific oil sludge such as macrostructure and chemical composition [8]. However, most of the methods are expensive, requiring a long time and even causing secondary pollution of the environment [6]. Based on the analysis of literature data extraction of sludge by a solvent is the most effective method of extracting petroleum among the listed methods, which is characterized by low energy costs [7]. In connection with the foregoing the authors of this paper had aim to analyze the oil sludge and offer the most effective solvent or solvent system for recovering petroleum products by the extraction method based on the data obtained. A sample of oil sludge taken from the storage tank of straight-run heavy fuel oil of «Pavlodar Oil Chemistry Refinery» LLP was selected as a research object of this work.

Experimental

The composition of the sludge was determined by the gravimetric method. A sample of oil sludge (10 g) was dried to constant mass in a thermal oven at 105 ºC. The weight loss of the sample was corresponded to the water content of the sludge. The water content determined by the described method corresponds to the water content obtained by the Dean-Stark Method (State standard 2477–65). The content of
petroleum products in the sludge was calculated from the weight loss of the sludge sample subjected to heat treatment in a muffle furnace at 600 °C. A sample of oil extracted from the sludge was analyzed for the content of silica gels (State standard 11858–66), paraffins (State standard 11851–85), resins and asphaltenes (State standard 11858–66*).

Results and discussion

It was noted that oil from the sludge is characterized by a relatively large content of silica gel resins (R) and paraffins (P) 4.67 wt. % and 6.88 wt. % respectively. The content of asphaltenes (A) 1.98 wt. %. It is known that, depending on the ratio \((R + A) / P\), oil sludge stabilizers can be subdivided into the following types, namely, asphaltene \((R + A) / P \geq 1.0\); paraffin \((R + A) / P \leq 1.0\); mixed \((R + A) / P \approx 1.0\). The stabilizers of the sludge investigated were assigned to the paraffin type based on the data obtained.

The group composition of isolated paraffins, resins and asphaltenes were studied by IR spectroscopy at 20 °C on a Cary 660 FT-IR spectrometer (Fig. 1). From the IR spectrum of paraffin (Fig. 1a) it can be seen that its composition contains an intense set of absorption bands in the 2920 and 2852 cm \(^{-1}\) region that corresponds to stretching vibrations of C–H bonds of methyl and methylene groups. The absorption bands in the 1464 cm \(^{-1}\) region are due to bending vibrations of \(-\text{CH}_2\) and \(-\text{CH}_3\) groups. The absorption band in the region of 1271 cm \(^{-1}\) indicates the presence of unbranched paraffin chains [9]. It follows from Figure 1 that the resin is characterized by a high content of C–H bonds of saturated hydrocarbons in the regions of the absorption bands 1377, 1459, 2861, 2922 cm \(^{-1}\). The absorption bands in the IR spectra of 1018 and 1704 cm \(^{-1}\) indicate the presence in the samples of both aromatic structures and carbonyl groups. Asymmetric and symmetrical oscillations of \(-\text{CH}_3\) and \(-\text{CH}_2\) groups at 2926, 2857 cm \(^{-1}\) are observed in the spectrum of asphaltenes (Fig. 1c). The absorption bands around 1700 cm \(^{-1}\) are due to the presence of carbonyl groups.

Figure 1. FT-IR spectra of components of oil sludge

Figure 2 presents photographs of samples of oil sludge before and after calcination. Figure 2a shows that oil sludge is a mass of black color. The sample acquired a ginger color and became crumbly after calc-
nation at 600 °C (Fig. 2b). Thus, it can be concluded that all petroleum products are oxidized and burned during calcination at temperature of 600 °C.

Figure 2. Photographs of oil sludge before and after calcination

Oil sludge investigated was analyzed on TG/DSC to obtain information on the initial and final temperature of thermal decomposition. The studies were performed on a differential scanning calorimeter DSC 131 evo from Setaram at a temperature range from 25 °C to 900 °C. The scanning was performed at a velocity of 20 °C/min. The results of the analysis are shown in Figure 3.

![Thermogram of the oil sludge](image3.png)

Figure 3. Thermogram of the oil sludge

Several stages of mass loss can be observed from the curves of TG and DSC of oil sludge shown in Figure 3 at temperatures below 160 °C, the mass loss on the TG curves corresponds to the evaporation of moisture and light components whose boiling points are below 160 °C [6]. The thermogram shows the boiling range of the aqueous phase at a temperature of 94.6 °C. The mass loss during the evaporation of light-boiling components was 10.69 %. The largest loss of mass (17.88 %) is observed at temperatures from 158.3 °C to 578 °C. The exothermic peak (280–578 °C) with a maximum at 450 °C, according to the literature [9], refers to the oxidative cracking of hydrocarbons. The loss of mass observed above 600 °C is determined by the thermal decomposition of some inorganic mineral substances [10]. Using this method of research, it was shown that oil products are completely burned to a temperature of 600 °C. Thus, the calcination temperature was found to determine the content of petroleum products in the oil sludge.
Determination of the phase composition of mechanical impurities isolated from oil sludge calcined at 600 °C for 1 hour of oil sludge was carried out by X-ray diffraction analysis using a D8 Advance X-ray diffractometer (Bruker).

### Table 1

<table>
<thead>
<tr>
<th>Name</th>
<th>Formula</th>
<th>Content, %</th>

<tr>
<td>Kaolinite</td>
<td>Al₂O₃·2(SiO₂)·2H₂O</td>
<td>2.9</td>
</tr>
</tbody>
</table>

According to the data obtained (Table 1), the main constituents of the mineral part of the oil sludge are quartz sand (63.1 %) and albite (16.5 %), silicates (6.9 %), magnetite (6.4 %), muscovite (4.1 %), kaolin (2.9 %). The mineral part of the oil sludge investigated, according to the results of the study, is suitable for use as components of building materials.

Thus, on the basis of a complex analysis of oil sludge, it was determined that the water content in the oil sludge under investigation was 12.4 wt.%, the content of oil products was 17.6 wt.% and mechanical impurities was 70 wt.%. As it is known from the literature [3] oil recovery is the most preferred option for the processing of oil sludge, it is noted that it is economically feasible to process sludge containing more than 10 mass% of oil. Extraction-gravimetric method for oil sludge was used to select solvents that have an optimal ratio of dissolving power and the ability to break conglomerates of sparingly soluble components into small fragments.

<td>97.44</td>
</tr>
</tbody>
</table>

According to the results obtained (Table 2), the most effective solution for dissolving the sludge is a mixture of solvents such as white spirit with hexene, the degree of recovery of petroleum products with this mixture was 97.44 % while in white spirit, which is a mixture of liquid aliphatic and aromatic hydrocarbons the recovery rate does not exceed 71 %. Good results were obtained using a solvent 646, in which toluene, butyl acetate, acetone, butanol, ethyl alcohol are present. The recovery rate of oil products was 96.99 %. Petroleum ether was the least effective solvent as it is a mixture of light aliphatic hydrocarbons; the content of dissolved petroleum products in it was 63.13 %. It can be noted that an increase in the efficiency of solvents is observed when an unsaturated hydrocarbon (hexene) is added to them.

A series of experiments were carried out to select the optimal ratio of hydrocarbons in white spirit: hexene mixture in order to extract oil products from oil sludge efficiently. Mass ratio of oil sludge : solvent was held at 1:4 and the dissolution time was 1 hour. The maximum yield of petroleum products 17.15 % by weight was observed at a volume ratio of white spirit : hexene 95:5. In this connection, for a given ratio of a mixture of hydrocarbons, studies were carried out on the selection of the oil sludge: solvent optimal ratio.
The data indicate that for the oil sludge and solvent mixture of white spirit: hexene (95:5) the ratio 1:4 is optimal.

Conclusions

Thus, an analysis of oil sludge from a storage tank for straight-run fuel oil was carried out. According to the TG/DSC analysis, it was found that water evaporation occurred at 94.6 °C, mass loss in the 158.1–578.3 °C region corresponds to the combustion of organic substances, and at a higher temperature, some inorganic mineral compounds are expected to decompose. It is established that the mineral part of the oil sludge was mainly represented by quartz. The most optimal mixture of solvents for extracting petroleum products from oil sludge was extracted using the extraction method. The best results were obtained by using a mixture of white spirit: hexene in a weight ratio of 95:5, the ratio of oil sludge: solvent 1:4. At this ratio, the recovery of oil from the sludge was almost 98 %.

Анализ нефтяного шлама и подбор растворителей для экстракционного метода извлечения нефтепродуктов

В статье проведен анализ нефтяного шлама ТОО «ПНХЗ», отобранного из резервуара хранения размолого мазута. Содержание воды, нефтепродуктов и механических примесей составило 12,4%, 17,6% и 70% соответственно. Образец нефти, выделенный из шлама, был проанализирован на содержание силикателевых смол, парафинов и асфальтенов, а также был изучен их групповой состав с помощью метода ИК-спектрометрии. Выявлено, что стабилизаторы нефтелама относятся к парафиновому типу. Для получения информации о начальной и конечной температурах термического разложения исследуемого нефтелама был использован TG/DSC анализ. Было показано, что нефтепродукты полностью сгорают до температуры 600 °C. Данная температура используется для проведения обширного нефтелама. Определен фазовый состав механических примесей, выделенных из нефтелама, методом рентгенографического анализа на рентгеновском дифрактометре D8 Advance (Bruker). По полученным данным выявлено, что основными составляющими минеральной части нефтелама являются кварцевый песок (63,1%) и альбит (16,5%). Была подобрана наиболее оптимальная смесь растворителей для извлечения нефтепродуктов из нефтелама экстракционным методом. Лучшие результаты были получены при применении смеси уайт-спирит : гексен.

Ключевые слова: нефтяной шлам, механические примеси, растворитель, экстракция, парафины, смолы, асфальтены, ТГ/ДСК анализ.
